Future Clinical Goals and Progress

For many centuries, dwarfs have been considered medical and social curiosities. In ancient cultures, these profoundly short and deformed individuals, who possessed an aura of mystery, were highly valued and even deified. People of the middle ages saw them as the keepers of jewels and jesters for royalty, and they played a prominent role in the literary folklore and mythology of American and many European cultures.† Dwarfs became particularly prominent in the entertainment field in the early 1900s. In the latter half of this century they have attempted to integrate into mainstream society despite the pressures of a culture that places a premium on conventional beauty, body proportions, and height.‡ The physiognomy and the frequently associated physiologic abnormalities of the respiratory, circulatory, and neurologic systems of dwarfs dictate, however, that from an anesthesiologist’s point of view, they must be considered different from the norm.¶

This review provides an overview of the classification of the syndromes associated with dwarfism and a discussion of the disturbed physiology of the respiratory, cardiovascular, neurological, and other organ systems. An understanding of this pathophysiology will facilitate the delivery of safe anesthesia in this group of patients.

Classification

Patients with dwarfism must not be regarded as having a single disease entity. There are, in fact, greater than 100 different types of dwarfism, many of which have specific implications for the anesthesiologist. Although each particular disorder is relatively rare (for instance, achondroplasia, the most common, occurs in only approximately 1.5 per 10,000 births), the large number of dwarfs ensures that any practicing anesthesiologist is likely to encounter these patients. Indeed, in 1989, Scott estimated that there were 55,000 dwarfs in the United States.§

People with severe short stature have generally been divided into two categories: 1) those with proportionate growth and a normal ratio of trunk-to-limb length (formerly called “midgets” which now is considered a derogatory term) and 2) those with short stature and disproportionate development, characterized either by short limbs or short trunks that in many cases are deformed. Those in the latter group are referred to as “dwarfs”.

Most proportionately short-statured persons are not dysmorphic and do not pose anesthetic problems aside

from those associated with an underlying etiologic disease. Their growth deficiency is caused either by constitutional factors or by various endocrine deficiencies, metabolic disorders, or chronic cardiac, renal, neurologic, or gastrointestinal diseases. In other normally proportioned patients, short stature is a component of a dysmorphic syndrome of unknown cause or is associated with chromosomal abnormalities. Only a small number of these syndromes—for instance, the Smith-Lemli-Opitz syndrome (tiny mouth) or the Russel-Silver syndrome (micrognathia)—have important anesthetic implications.

In this review, we emphasize the anesthetic management of patients with disproportionate short stature—a manifestation of congenital, generalized, diseases of bone which present problems during or after anesthesia.

Under the International Nomenclature of Constitutional Diseases of Bone, disorders that produce disproportionate short stature are found in the osteochondrodysplasias (abnormalities of cartilage and/or bone growth and development) and in a group of primary metabolic diseases that involve the skeleton. Abnormal bone growth that predominantly affects the axial skeleton produces short-trunk dwarfism, whereas a greater involvement of the appendicular skeleton characterizes short-limb dwarfism.

The nomenclature of the osteochondrodysplasias frequently reflects the clinical and roentgenographic features of the dysplasia (table 2). Rhizomelia, mesomelia, and acromelia describe limbs in which the shortening involves the proximal, middle, or distal segments, respectively. The names of some dysplasias are derived from the Greek terms describing the phenotype. For example, diastrophic dysplasia, from the Greek “diastrophos” meaning “tortuous, twisted,” refers to the kyphoscoliosis and deformed extremities that are prominent features of this dysplasia. Camptomelic dysplasia, characterized by severe extremity deformities, is derived from the Greek “camptos,” meaning “bent,” and “melos,” meaning “limb”.

Since dwarfs tend to have several abnormalities that have anesthetic implications, we offer a general approach to the preoperative evaluation and suggest guidelines for the anesthetic management of these patients. The appendix summarizes the clinical manifestations and the anesthetic implications of the more common syndromes associated with dwarfism.

**Anatomic and Physiologic Abnormalities Associated with Dwarfism**

**AIRWAY ABNORMALITIES**

The anesthetic management of a variety of dwarfs is frequently complicated by upper airway obstruction and difficulties with direct laryngoscopy, problems that are major causes of perioperative morbidity and mortality.

The anesthesiologist caring for the patient with one of the mucopolysaccharidoses (MPS) (most notably MPS IH, MPS IH/IS, MPS II, MPS IV, MPS VI) (table 2) is frequently challenged by a difficult airway that tends to become obstructed with sedation or general anesthesia. Copious nasal secretions, a large tongue, large tonsils and adenoids, stiff temporomandibular joints, thickened pharyngeal and laryngeal structures, and narrowed nasal passages from mucopolysaccharide deposition lead to upper airway obstruction even in the unanesthetized state (fig. 1A, B), and contribute to difficulty in visualizing the larynx. Once the larynx has been exposed, tracheal narrowing from infiltration of glycosaminoglycans in some

MPS\textsuperscript{17-19} may make the passage of an endotracheal tube difficult (fig. 1A). In contrast, although the patient with achondroplasia may have narrow nasal passages and pharyngeal hypoplasia as a result of dysplasia and angulation of the cranial base and hypoplasia of the maxilla, his airway can readily be managed with a face mask.\textsuperscript{20}

Other airway anomalies, such as laryngomalacia, chondrodysplasia punctata,\textsuperscript{21} diastrophic dysplasia,\textsuperscript{22} and camptomeric dysplasia, laryngotracheal stenosis (rarely in spondyloepiphysial dysplasia),\textsuperscript{23} and micrognathia (mesomelic dysplasia, severe diastrophic dysplasia, and Russel-Silver syndrome)\textsuperscript{24} can contribute to upper airway obstruction. Airway patency may, in addition, be affected by position. Some patients with achondroplasia,\textsuperscript{25} Morquio syndrome,\textsuperscript{26} and metatropic dysplasia\textsuperscript{27} maintain a patent airway with the neck extended whereas flexion produces airway obstruction.

Cervical abnormalities contribute to difficult laryngoscopies. Dwarfs with short necks (Morquio syndrome, metatropic dysplasia, or spondyloepiphysial dysplasia) or with cervical kyphosis (diastrophic dysplasia) are particularly difficult to intubate.\textsuperscript{5,11} The sternal prominence associated with pectus carinatum in Morquio syndrome, metatropic dysplasia, and forms of spondyloepiphysial dysplasia can interfere with the midline positioning of the laryngoscope. Odontoid hypoplasia with cervical instability, or the presence of cervical traction or other stabilization devices that limit neck extension, make direct laryngeal exposure difficult. Although occasional abnormalities of the base of the skull may limit neck extension, only rarely does this interfere with laryngoscopy and intubation.\textsuperscript{16}

### Pulmonary Abnormalities

Respiratory symptoms and dysfunction occur frequently in dwarfs, particularly when they are children. Several pathologic entities are responsible for these respiratory complications. Thoracic cage dystrophy from rib hypoplasia\textsuperscript{25,29,30} and progressive kyphosis, scoliosis.

---

![Fig. 1. (A) Sagittal thoracic magnetic resonance image of a 35-yr-old patient with Hunter-Scheie syndrome who developed severe airway obstruction after sedation for planned fiberoptic intubation. Note thickened, indurated epiglottis (a), marked glottic and subglottic narrowing (b), and diffuse tracheal stenosis (c). and thoracic lordosis cause most of the cases of restrictive lung disease. Sleep apnea, with obstructive, central, and mixed components, \(^{25,31-34}\) leads to substantial morbidity and even sudden death. \(^{35-39}\) Structural abnormalities, with thickening and narrowing of the walls of the trachea and bronchi, particularly in the MPS, may be responsible for intrathoracic obstruction. \(^{17-19,40}\) Coincidental chronic pulmonary diseases, such as asthma, recurrent atelectasis, chronic aspiration, and pneumonia can also contribute to respiratory morbidity. \(^{25}\)

**Restrictive Lung Disease**

The small narrow chest wall of thoracic dystrophy from rib hypoplasia is associated in its worst form with lethal entities such as thanatophoric dwarfism, Saldino-Noonan syndrome, and Majewski syndrome. \(^{22}\) Less severe forms of this deformity are responsible for restrictive pulmonary dysfunction in many other types of dwarfs, including those with achondroplasia, \(^{25}\) chondroectodermal dysplasia, \(^{21,28}\) Jeune syndrome, \(^{26,29}\) metatropic dysplasia, \(^{27}\) and campomelic dysplasia \(^{41}\) (fig. 2). Whether lung hypoplasia with reduced number of bronchioles and alveoli is associated with thoracic dystrophy and contributes to impaired lung function remains to be investigated. Preliminary evidence suggests, at least in Jeune syndrome, that it may be a factor. \(^{42}\) Of the above syndromes, achondroplasia is by far the most likely to be encountered by the anesthesiologist. Thoracic dysplasia in achondroplasia is a problem essentially confined to young children. \(^{25}\) In a study that included measurements of chest wall dimensions in adults with achondroplasia, Stokes et al. \(^{43}\) demonstrated no difference from that of average-statured control patients in the shape of the adult achondroplast thorax, except for a slight reduction in the anteroposterior chest diameter in men.

Scoliosis and/or kyphosis is a common clinical finding in dwarfs. \(^{44}\) Spinal deformity must be moderately severe before it interferes with respiratory function. Such severe scoliosis frequently develops in diastrophic and metatropic dysplasia and in some forms of osteogenesis imperfecta (figs. 3 and 4). Less severe scoliosis develops in patients

**Fig. 3. Chest radiograph of a 12-yr-old girl with diastrophic dysplasia, chronic respiratory insufficiency, and moderate compression myelopathy. Note the “syphon-shaped” extremely severe, thoracic kyphoscoliosis.**
DWARFISM: ANESTHETIC IMPLICATIONS

FIG. 4. Lateral chest and abdomen radiograph of a 12-yr-old boy with metatropic dysplasia and chronic respiratory failure. Note the severe narrowing of the transverse dimension of the chest due to rib hypoplasia. The spinal segment between the distal end of an occipito-C3 fusion and the L1-L2 fusion progressively developed a horizontal “swan-neck” deformity. The thoracic spine (T1-T10) became ankylosed almost parallel to the diaphragm, compressing the lungs into a small wedge.

with camptomelic dysplasia, pseudoachondroplastic dysplasia, spondyloepiphyseal dysplasia congenita, and spondyloepiphyseal dysplasia. Thoracic lordosis cephalad to thoracolumbar kyphosis also compromises respiratory function in patients with achondroplasia and MPS I, II, and IV. Only restrictive lung disease with reduced vital capacity and functional residual capacity characterizes thoracic dystrophy and kyphoscoliosis. These reduced lung volumes predispose toward airway closure accompanied by subsequent ventilation perfusion mismatching, increased alveolar-arterial gradient, and recurrent, scattered atelectasis. Only with advanced, severe restrictive disease does hypoventilation with retention of carbon dioxide develop. Interference with normal intercostal muscle function may also contribute to the disturbed physiology. Massive hepatosplenomegaly in some patients with MPS and the exaggerated thoracolumbar lordosis or gibbus formation observed in some patients with skeletal dysplasias can compromise diaphragmatic motion and aggravate the restrictive defect. Interstitial pulmonary deposition of glycosaminoglycans contribute to both the restrictive disease and a diffusion deficit. In patients with MPS, recurrent atelectasis and aspiration of purulent nasopharyngeal secretions predispose patients to recurrent, potentially life-threatening pneumonias.

Tracheobronchial Obstruction

In addition to upper airway obstruction and restrictive lung disease, positionally dependent or fixed intrathoracic airway obstruction is now recognized as an important cause of respiratory morbidity and even death in patients with MPS, particularly MPS IH, II, IV, and VI. Narrowing of the trachea and mainstem bronchi to produce airway compromise can result from focal enlargement and thickening of tracheal rings and thickening of the mucosa and periluminal connective tissue by glycosaminoglycan deposition (fig. 1A). Tracheobronchial narrowing may even occur below the level of a tracheostomy that has been performed because of upper airway obstruction. Peters et al. demonstrated that 15% of patients with MPS have an abnormally narrow trachea, a finding that can be easily observed from a frontal chest radiograph.

Sleep Apnea

Sleep apnea with obstructive, central, or mixed components has become recognized as an insidious but treatable cause of severe morbidity and even death in some dwarfs, and especially in children. It has been described with several different types of dwarfism but appears to be of particular importance in patients with achondroplasia, metatropic dysplasia, and several of the MPS. Obstructive sleep apnea is more common than central apnea in patients with achondroplasia. Abnormal craniofacial bone growth that results in brachycephaly, facial and pharyngeal hypoplasia, flattening of the nasal bridge, and constricted upper airways causes upper airway obstruction in achondroplasia. Hypoplasia of muscles of the upper airway, a component of the generalized hypoplasia common in young children with achondroplasia, may also contribute to functional upper airway obstruction during sleep. Obstructive sleep apnea in patients with MPS also demonstrates both fixed and dynamic components of obstruction. The causes of upper airway obstruction in these patients have been discussed above and include macroglottia, tonsillar and adenoidal enlargement, and infiltration of the pharyngeal mucosa and laryngeal structures with glycosaminoglycans.

Central apnea in patients with achondroplasia is caused by compression of the distal medulla and upper cervical cord at the craniovertebral junction by foramen magnum stenosis (see the section on neurologic abnormalities, below). Episodes of central apnea and hypoxia in these patients can be occult, without other clinical evidence of
Cardiac Abnormalities

Cardiovascular abnormalities, both congenital and acquired, frequently confront the anesthesiologist responsible for the anesthetic management of dwarfs.\textsuperscript{41,48,49} Congenital Heart Disease

Atrial septal defect, ventricular septal defect, or cleft mitral valve occur more frequently in patients with chondroectodermal dysplasia than in the general population.\textsuperscript{22} An atrial septal defect is an anomaly occasionally associated with Robinow mesomelic dysplasia and with camptomelic dysplasia.\textsuperscript{5}

Valvular Heart Disease

Aortic root dilatation, aortic insufficiency, and mitral valve prolapse occasionally occur in patients with osteogenesis imperfecta.\textsuperscript{48,50,51} In some patients with MPS, collagen and fibroblasts distended with glycosaminoglycans lead to valvular thickening with insufficiency and/or to stenosis and calcification at an early age.\textsuperscript{19,48,52} Patients with MPS IH (Hurler syndrome) and MPS II (Hunter syndrome) frequently have both mitral and aortic regurgitation, although the tricuspid and pulmonary valves rarely become involved.\textsuperscript{19,52-54} Severe infiltrative valvular involvement is less common in MPS IV (Morquio syndrome), but aortic insufficiency has been noted.\textsuperscript{19,52} Severe aortic stenosis has been described in patients with MPS VI (Maroteaux-Lamy syndrome).\textsuperscript{56}

Cardiomyopathy

In addition to valvular disease, some dwarfs with MPS can develop a cardiomyopathy as a result of glycosaminoglycan deposition in the myocardium. Others manifest asymmetric septal hypertrophy.\textsuperscript{52,57}

Coronary Artery Disease

In some patients with MPS, particularly in those with MPS IH and II, concentric intimal and medial thickening of extramural coronary arteries, by storage cells containing glycosaminoglycans, can lead to severe narrowing and ischemic heart disease.\textsuperscript{55} Brosius and Roberts\textsuperscript{58} found at necropsy that five of six children with MPS IH had greater than 75\% narrowing in one or more coronary arteries. These findings may explain why half of the deaths in patients with MPS IH are due to sudden cardiovascular collapse or progressive congestive heart failure.\textsuperscript{53,55}

Pulmonary Hypertension

Pulmonary hypertension, leading to cor pulmonale, is probably the most common cardiovascular disturbance that develops in dwarfs. Restrictive lung disease,\textsuperscript{26,59} congenital heart disease with left-to-right shunts,\textsuperscript{60} chronic upper airway obstruction,\textsuperscript{61,62} and sleep apnea all contribute to the development of pulmonary hypertension and cor pulmonale in dwarfs. Chronic upper airway obstruction is associated with pulmonary hypertension, although the pathophysiology is not clearly understood. Chronic or recurrent hypoxemia, carbon dioxide retention, and negative intrathoracic pressures with increased vascular transmural pressures and increased left and right ventricular afterload all may play a role.\textsuperscript{63} Pulmonary hypertension can also be due either to increased pulmonary blood flow from a left-to-right intracardiac shunt or to a reduction in the cross-sectional area of the pulmonary vascular bed that leads to increased pulmonary vascular resistance.\textsuperscript{64} The latter results from either fixed, structural changes of the pulmonary vascular bed (which occurs with severe thoracic dystrophy)\textsuperscript{42} or from reactive, partially reversible pulmonary arterial vasoconstriction in response to a variety of stimuli such as hypoxia, hypercarbia, and acidosis. Carefully planned and performed anesthesia in patients with pulmonary hypertension can prevent acute elevations of pulmonary arterial pressure that initiate a vicious cycle of right-sided heart failure, decreasing cardiac output, myocardial ischemia, acidosis, and further aggravation of pulmonary hypertension.\textsuperscript{60,64}

Neurologic Abnormalities

The two major categories of neurologic complications commonly associated with dwarfism are hydrocephalus and compressive spinal cord and nerve root syndromes. Compression of the spinal cord and nerve roots may result from one or more of the following lesions: foramen magnum stenosis, odontoid hypoplasia with cervical instability, thoracolumbar and generalized spinal stenosis, and severe kyphosis and scoliosis. Common surgical procedures to alleviate the neurologic symptoms include suboccipital craniectomy for foramen magnum stenosis, laminectomy for spinal stenosis, cervical fusion for cervical instability, and ventriculoperitoneal shunts for hydrocephalus.

Macrocephaly and Hydrocephalus

The disproportionately large head that so frequently is a finding in the patient with achondroplasia may be a
reflection of macrocephaly, hydrocephaly, or both. Macrocephaly results from an accelerated rate of head growth and is generally accompanied by mild dilation of the ventricles, but without elevated intracranial pressure.\textsuperscript{65,66} Macrocephaly, in contrast to hydrocephaly, has no physiologic implications for the anesthesiologist. Progressive hydrocephalus with signs of elevated intracranial pressure (ICP) may necessitate decompressive ventriculoperitoneal shunting.\textsuperscript{65} Hydrocephalus in patients with achondroplasia is probably due to intracranial venous hypertension\textsuperscript{67-69} or to obstruction of the cerebrospinal fluid pathways at the level of the foramen magnum. It usually is associated with other neurologic signs of cervical cord compression.\textsuperscript{65,68} Progressive hydrocephalus can also complicate the course of patients with MPS, particularly those with MPS IH and MPS II.\textsuperscript{19}

**Spinal Cord and Nerve Root Compression Syndromes**

Odontoid dysplasia, a frequent finding in many of the osteochondrodystrophies, is occasionally complicated by atlantoaxial instability and cord compression.\textsuperscript{70-76} The odontoid process arises perpendicularly from the superior surface of the body of the second cervical vertebra (C2) and lies in the facet of the anterior arch of the first cervical vertebra (C1). This allows the head to be flexed and extended on the neck. If the odontoid process is hypoplastic, C1 may dislocate anteriorly and cause spinal cord compression.\textsuperscript{79} Odontoid dysplasia with atlantoaxial instability occurs more frequently, although not exclusively, in syndromes primarily affecting the axial skeleton. Odontoid dysplasia and atlantoaxial instability are common in patients with Morquio syndrome, spondyloepiphysyeal dysplasia congenita, metatrophic dysplasia, and spondyloepiphyseal dysplasia, and occur less frequently in patients with chondrodysplasia punctata, MPS IH, MPS II, and multiple epiphyseal dysplasia.\textsuperscript{45,71-75}

Foramen magnum stenosis, thoracolumbar stenosis, and generalized spinal stenosis may develop in patients with achondroplasia.\textsuperscript{65,77-80} These spinal neurologic complications cause the majority of hospital admissions for achondroplastic dwarfs.\textsuperscript{77} Foramen magnum stenosis results from hypertrophy of the bony margins of the foramen magnum. An axial computerized tomographic (CT) study of 26 children with achondroplasia and neurologic or respiratory symptoms\textsuperscript{81} demonstrated that in 25 of 26 cases, the foramen magnum was smaller than 3 standard deviations from the mean for age-matched normal-stature controls. This bone encroachment narrows the upper cervical spinal canal and subarachnoid space, potentially impinging on the medulla and upper cervical cord.\textsuperscript{14,72,73} The compression of the cervico medullary junction can be demonstrated by CT, CT myelography,\textsuperscript{81,82} or magnetic resonance imaging (MRI).\textsuperscript{88} (fig. 5).

In thoracolumbar and generalized spinal stenosis, the spinal cord, conus medullaris, and cauda equina are compressed by a spinal canal that is narrowed either by abnormally shaped vertebrae or congenitally hyperplastic intervertebral discs.\textsuperscript{78} Endochondral bone formation is affected in achondroplasia and results in vertebral bodies that are abnormally shallow and vertebral arches that are considerably underdeveloped. As a result, the spinal canal is constricted throughout its length, a condition that leads to narrowing of the subarachnoid and epidural spaces.\textsuperscript{83} In addition, the congenitally hyperplastic intervertebral discs in persons with achondroplasia tend to bulge laterally and posteriorly. Multiple protruded discs are common in the adult achondroplastic dwarf. Disc prolapse into a congenitally stenotic canal may cause neural compression, usually involving the cauda equina.\textsuperscript{84} Neurologic presentations include acute or slowly progressing paraparesis, quadriplegia, sensory deficits, and sphincter dysfunction.\textsuperscript{85,86} Severe thoracic or lumbar kyphoscoliosis and cervical scoliosis only infrequently produce cord compression.

**Abnormalities of Thermal Regulation**

Patients with osteogenesis imperfecta (OI) display evidence of a generalized disturbance of energy metabolism.\textsuperscript{87,88} This hypermetabolic state is characterized by episodic elevations of body temperature, elevated oxygen consumption, and diaphoresis. The increased heat and oxygen consumption has been attributed to an uncoupling of oxidative phosphorylation with increased adenosine triphosphate (ATP) breakdown.\textsuperscript{87-89} This produces elevated serum pyrophosphate levels, a frequent laboratory finding in these patients.

Under anesthesia, patients with osteogenesis imperfecta\textsuperscript{90-92} occasionally manifest a rise in body temperature. These episodes are not associated with features of malignant hyperthermia such as muscle rigidity, arrhythmias, metabolic and respiratory acidosis, or hyperkalemia, and should not be diagnosed as malignant hyperthermia.\textsuperscript{90,91} Atropine has been blamed for temperature elevation in patients with OI and in other dwarfs, but such an adverse effect is not proven.\textsuperscript{93}

**Coagulation Abnormalities**

Although not a problem with other osteochondrodystrophies, some patients with OI demonstrate easy bruising and a mild bleeding tendency that is not usually a clinical problem during surgery.\textsuperscript{94} Several case reports, however, describe substantial postoperative bleeding in OI patients after open heart surgery.\textsuperscript{95-97} The precise nature of this coagulopathy is not defined. Hathaway et al.\textsuperscript{94} have demonstrated that this bleeding diathesis is caused by platelet dysfunction, which may be another
manifestation of altered ATP metabolism. This coagulopathy is characterized by one or more of the following abnormalities on in vitro tests of platelet function: defective release of platelet factor III and impaired platelet aggregation to ADP, or, less frequently, impaired aggregation in collagen stimulation. Approximately 30% of patients with OI also demonstrate prolonged bleeding time, enhanced capillary fragility, decreased platelet retention, and a reduction of factor VIII. These studies indicate that tissue friability, platelet aggregation abnormalities, and coagulation factor deficiencies all play a role in the hemostatic defect of patients with OI.

**Psychosocial Considerations**

Although the literature on the medical management of dwarfs is extensive, there are few studies that examine the psychosocial consequences of being profoundly short. The studies that do exist have tended to evaluate patients with achondroplasia, hypopituitarism, or constitutional short stature, although there are more than 100 different types of dwarfism. Although it is frequently assumed that patients with disproportionate short stature are retarded, numerous studies have demonstrated a normal range of intelligence in many dwarfs. Motor milestones in early childhood may be delayed, and some dwarfs, particularly those with hypopituitarism, lag in psychosocial maturity. A very important concern in dealing with dwarf patients, particularly with older children and adults, is the need to avoid infantilization. The interaction of the anesthesiologist with the patient must be appropriate to the age of the patient regardless of the patient’s height. This may require a conscious effort, since the typical response of an averaged-sized person is to relate age and maturity to height and not to chronologic age.

**Anesthetic Management**

**GENERAL CONSIDERATIONS**

An understanding of the multiple abnormalities that affect dwarfs will facilitate the safe delivery of anesthesia in these patients. Monitoring and anesthetic techniques for optimal care should be dictated by the type of dwarf, the anatomic and physiologic aberrations of different organ systems, and the nature of the surgical procedure.

Although the potential for airway obstruction in some dwarfs is well-recognized, general anesthesia has traditionally been the technique of choice. This may, in part, be due to technical challenges encountered during the performance of spinal and epidural anesthesia in many of these patients. These difficulties result from a variety of spinal anatomical abnormalities, such as severe lordosis, kyphoscoliosis, and malformed vertebral bodies. In patients with achondroplasia, prolapsed intervertebral discs and a relatively narrow spinal canal may exist in addition to these anatomic abnormalities. There are, however, several case reports of successfully performed spinal and epidural anesthetics for cesarean section in patients with several types of dwarfism, including achondroplasia, osteogenesis imperfecta, and spina bifida.

Accurate blood pressure measurement mandates the use of an appropriately sized blood pressure cuff, which should cover two thirds of the length of the upper arm.
Cuffs smaller than those usually used for average-sized patients of the same age must be used in rhizomelic dwarfs (achondroplasia or diastrophic dysplasia). In patients with severe OI, invasive blood pressure measurement by arterial cannulation may be preferable to the use of a blood pressure cuff, to reduce the risk of humeral fractures.

Establishing central or peripheral vascular access in dwarfs is often difficult. Obesity and the thickened, indurated subcutaneous tissues of patients with MPS make identification of veins and insertion of intravenous catheters a challenge. Cervical abnormalities in some dwarfs, including very short necks, cervical scoliosis, and the presence of a cervical stabilizing device, may make jugular vein cannulation difficult or even impossible; in such instances, the anesthesiologist may be compelled to use either femoral or subclavian veins for central line placement. Subclavian vein cannulation may also be unsuccessful or even hazardous, particularly when the upper thoracic anatomy is distorted by severe thoracic scoliosis and kyphosis.

Guidelines for the selection of the appropriately sized endotracheal tube for dwarfs are unclear. Review of the data for patients with achondroplasia by Mayhew et al. suggests that the age-based formula for selecting endotracheal tube size for children (tube size [mm ID] = [age (yr) + 16]/4) usually predicts the correct endotracheal tube size. No information is available in regard to the size of endotracheal tubes that should be used for other types of dwarfs.

**AIRWAY DYSFUNCTION**

**Preoperative Evaluation**

In addition to knowledge of the airway abnormalities that might exist, a careful search for symptoms of obstructive sleep apnea will alert the anesthesiologist to patients who are likely to develop upper airway obstruction after sedation or the induction of general anesthesia. All available prior anesthetic records should be reviewed for information about airway management, such as difficulty with a mask airway or with laryngoscopy and intubation. Dwarfs born with short necks (spondyloepiphyseal dysplasia congenita, camptomelic dysplasia, or diastrophic dysplasia) may have a history of traumatic or prolonged perinatal intubation, which may have lead to subsequent subglottic stenosis. A physical examination of the airway should include evaluation of the size of the tongue, mouth, and mandible. Particular attention should be paid to evaluating the position of the larynx, the shortness of the neck, and the mobility of neck and jaw. Cervical spine stability must be assessed, since odontoid hypoplasia is observed in many different dwarfs. This evaluation is discussed in detail in the section on neurologic dysfunction.

The clinical impression of an anatomically abnormal upper airway or of tracheal narrowing should be confirmed by one or more of the following studies: lateral neck radiographs, xerography, tomography, CT scanning, or MRI techniques. If the patient seems to have structural abnormalities of the larynx or trachea (such as tracheobronchial narrowing from glycosaminoglycan infiltration in patients with MPS, or tracheomalacia in children with diastrophic dysplasia), then preoperative fiberoptic airway endoscopy by an anesthesiologist or otolaryngologist skilled in the technique is helpful in defining the etiology, site, and extent of airway compromise (fig. 1B). The degree of functional extrathoracic or intrathoracic obstruction can be evaluated by flow-volume loops. Since neck flexion may aggravate the airway obstruction in patients with achondroplasia, metatropic dysplasia, or MPS, these flow-volume loops should be performed in positions of neck flexion and extension.

**Anesthetic Management**

Preoperative sedation should be avoided if the potential for upper airway obstruction exists. Atropine or glycopyrrolate should be administered preoperatively if excessive oral and nasal secretions are present, if a difficult airway is anticipated, or if a fiberoptic intubation is planned. Intravenous access should be established before induction in patients in whom airway problems are likely. Both awake intubation and inhalational induction with oxygen and halothane, while spontaneous ventilation is maintained, are relatively safe anesthetic techniques, if difficulty in maintaining a patent airway or in intubating the trachea is anticipated. Muscle relaxants should be avoided until positive-pressure ventilation by mask can be ensured. It is important to avoid neck manipulation, particularly positions of neck flexion during laryngoscopy in patients with atlantoaxial instability or foramen magnum stenosis. A subsequent section on the anesthetic management of the dwarf with neurologic complications reviews in detail the appropriate positioning and airway management of patients with cervical cord compression and instability.

Laryngeal exposure may be impossible with a conventional laryngoscope in some dwarfs with very short necks and with a severe pectus carinatum chest deformity (such that the head appears to rest upon the chest) because it is not possible to rotate such a laryngoscope to the midline. A laryngoscope with a very short handle may be useful in these cases. If the glottis cannot be exposed by direct laryngoscopy, then fiberoptic intubation with the patient awake or under general inhalational anesthesia during spontaneous ventilation is indicated. Particular care must be exercised in sedating a patient with upper airway obstruction for an awake endoscopy, in order to avoid pre-
pitting complete airway obstruction. In children breathing spontaneously under general anesthesia, anesthetic gas and oxygen can be provided through one nostril and the bronchoscope and endotracheal tube manipulated through the other, or a mask with an endoscopic port may be used. A blind nasal intubation technique may be useful in some situations, although it may cause troublesome pharyngeal bleeding, especially in patients with MPS who have enlarged adenoids. Retrograde passage of a guide wire through the cricothyroid membrane is another option when visualization of the larynx is impossible.

Even with a careful inhalational technique, anesthetic induction in a dwarf with upper airway obstruction and possibly with concomitant myocardial and pulmonary involvement is a high-risk undertaking. Complete upper airway obstruction that cannot be relieved by the usual aw thrust or chin lift maneuver or by an oral or nasal pharyngeal airway may develop, particularly in patients with MPS. Direct traction on the tongue, together with gentle neck flexion, can overcome airway obstruction caused by this enlarged organ. If severe upper airway obstruction is anticipated preoperatively, a surgeon or otolaryngologist skilled in emergency tracheostomy should be requested to be present during induction. Tracheostomy may be extremely difficult or even impossible without a concomitant thoracotomy in some patients with short necks and pectus carinatum deformity. A tracheostomy will not always completely relieve airway obstruction in some patients with advanced MPS because of considerable tracheal narrowing distal to the tracheostomy. Preoperative CT or MRI scanning and fiberoptic bronchoscopy will alert the anesthesiologist and otolaryngologist to the site and extent of the tracheobronchial stenosis.

PULMONARY DYSFUNCTION

Preoperative Evaluation

A comprehensive history, examination, and appropriate testing will aid in determining both the cause and the severity of respiratory dysfunction. Chest dimensions can be compared with accepted standards to quantitate the degree of chest wall hypoplasia. The degree of scoliosis and kyphosis can be determined radiologically. Spirometry, blood gas, hematocrit, and serum electrolyte determinations, as well as more sophisticated pulmonary function tests, such as diffusion capacity measurements, can help in quantitating the extent of underlying pulmonary involvement. The interpretation of spirometric measurement of lung volumes is complicated in dwarfs because there are no reference standards for these measurements in short-trunk dwarfs. Serial measurements, over time, if available, will provide the most information. Stokes et al. have recently published spirometric standards for asymptomatic adults with achondroplasia that are based on the sitting rather than the standing heights of the patients. Information about the dimensions of the intrathoracic tracheobronchial tree can be obtained from the chest radiograph, thoracic CT scan, or MRI (fig. 1A). The extent of functional intrathoracic obstruction can be diagnosed by inspiratory and expiratory flow-volume loops.

Attention should be directed toward eliciting a history of sleep-related breathing disorders such as snoring, apnea, cyanosis, restless sleep, chest retraction, paradoxical chest movements, and daytime somnolence. Multichannel polysomnography can be used to confirm these clinical suspicions. The cause of obstructive sleep apnea can further be determined by fiberoptic visualization of the upper airway by a competent otolaryngologist and by radiographic, CT, or MRI evaluation of the upper airway. Central apnea suggests cervicomедullary or cervical cord compression that can be appropriately evaluated with cervical radiographs in flexion and extension, CT myelography, MRI, and evoked potential monitoring. Apart from the potential risk of hypoxia and hypercarbia in the peroperative period, the most important complication of lung and airway involvement that influences anesthetic management is the development of pulmonary hypertension. The preoperative evaluation of this complication is discussed in the section on cardiovascular dysfunction.

Anesthetic Management

Anesthetizing a patient with pulmonary dysfunction, possibly accompanied by airway obstruction, pulmonary hypertension, or right ventricular compromise, presents the anesthesiologist with many challenges. Restrictive lung disease prolongs an inhalation induction that may already be compromised by upper airway obstruction. The low functional residual capacity and high closing volume in patients with restrictive lung disease tend to promote atelectasis and ventilation/perfusion mismatching. Low resting lung volumes reduce pulmonary reserve such that oxygenation may be easily compromised; in these cases high inspired concentrations of oxygen are required to maintain adequate arterial PaO₂. This respiratory dysfunction mandates the use of pulse oximetry and endtidal CO₂ monitoring. Arterial cannulation for intra- and postoperative blood gas analyses is recommended for all but the shortest and simplest of surgical procedures in any dwarf with significant respiratory disease. These patients may also require postoperative mechanical ventilation, which may be prolonged, particularly in patients with severe thoracic dystrophy (e.g., infants with Jeune syndrome).
CARDIOVASCULAR DYSFUNCTION

Preoperative Evaluation

The preoperative evaluation of cardiac dysfunction requires a comprehensive history, examination, chest radiograph, electrocardiography, and, in many cases, echocardiography. The expertise of a cardiologist is frequently needed, and a cardiac catheterization may be required to delineate the hemodynamic significance of valvular dysfunction, the extent of pulmonary hypertension and coronary artery disease, and the specific anatomy of congenital heart disease.

The detailed preoperative evaluation of patients with ischemic and valvular heart disease exceeds the scope of this review and is discussed elsewhere. Pulmonary hypertension, the most common cardiovascular complication of dwarfs, requires careful analysis. The typical signs of established pulmonary hypertension include a prominent parasternal heave, the auscultatory findings of a widely split second heart sound with a loud pulmonary component, a systolic pulmonary ejection murmur, and less frequently, an early diastolic murmur of pulmonary insufficiency. Chest radiography may reveal an enlarged heart with a prominent pulmonary artery segment, and in severe cases, peripheral “pruning” of the pulmonary arterial vasculature. Right ventricular enlargement and hypertrophy can be demonstrated by the electrocardiogram and echocardiogram. A prolonged right ventricular pre-ejection period also may be noted.

Anesthetic Management

The anesthetic management of patients with cardiac ischemia, valvular disease, pulmonary hypertension, and impaired myocardial function must be meticulously planned and executed. Appropriate monitoring includes continuous arterial and right atrial pressure measurement, and in severe cases, pulmonary artery catheterization. Endocarditis prophylaxis is necessary in patients with either congenital cardiac abnormalities or acquired valvular disease. The anesthetic management of dwarfs with pulmonary hypertension must be planned such that anesthetic agents and various other stimuli that aggravate pulmonary arterial vasoconstriction can be avoided, and yet adequate cardiac output and coronary perfusion pressure be maintained.

Hypoxic pulmonary vasoconstriction superimposed on pre-existing pulmonary hypertension may cause catastrophic reduction in right ventricular function. Both hypercarbia and acidosis have similar adverse hemodynamic effects. Respiratory and metabolic alkalosis can reduce pulmonary vascular resistance and pulmonary artery pressure. Regardless of the anesthetic agents used, an adequate depth of anesthesia must be maintained to prevent elevations of pulmonary artery pressure, which may develop under light anesthesia.

Nitrous oxide should probably be avoided in patients with pulmonary hypertension, since studies suggest that it increases pulmonary vascular resistance. Similarly, enflurane has been associated with a modest increase in pulmonary artery pressure; it is prudent to avoid the use of this agent in patients with pulmonary hypertension. Halothane and isoflurane may reduce pulmonary artery pressure and are therefore the inhalational agents of choice for these patients. Narcotics in high doses have little effect on the pulmonary circulation. In patients with right ventricular failure they are the preferred anesthetic agents since, unlike the inhalational agents, they do not depress myocardial function. Ketamine is useful in children with pulmonary hypertension or poor myocardial function. The safe use of ketamine in adults with pulmonary hypertension has not been established. In some studies of adults, an increase in pulmonary vascular resistance has been documented. Although the results of laboratory studies are conflicting, barbiturates do not appear to have a substantial selective effect on the pulmonary circulation.

In addition to avoiding hypoxia, acidosis, and anesthetic agents that aggravate pulmonary hypertension, the anesthesiologist must choose the anesthetic to maintain adequate cardiac output and coronary perfusion. When right ventricular function is compromised by increased right ventricular afterload, anesthetic agents with negative inotropic actions, such as halothane, are contraindicated, and either narcotics or ketamine (in children) should be chosen.

NEUROLOGIC DYSFUNCTION

Preoperative Evaluation

The neurologic manifestations of cervicomедullary compression are varied and may be suggested by a thorough history and physical examination. These manifestations include not only the typical findings of an upper motor neuron lesion, such as weakness, hyperreflexia, clonus, abnormal plantar responses, but also a spectrum of less well-appreciated, nonspecific respiratory symptoms and signs that are noteworthy in children and infants.

In children, apnea of central origin resulting from direct compression of the medulla and upper cervical spinal cord is a characteristic, relatively recently recognized symptom. Other nonspecific presentations, such as hypoxia without appreciated respiratory problems, respiratory distress, recurrent cyanotic spells, and even sudden infant death, are recognized as manifestations of cervicomедullary compression in infants and young children. The classic signs and symptoms of upper motor neuron
lesions may be difficult to elicit or may even be absent in infants and young children.\textsuperscript{34} Odontoid hypoplasia \textit{per se} does not necessarily imply atlantoaxial instability and cord compression. In dwarfs with cervical spine involvement, lateral radiographs of the cervical spine should be performed in positions of active, not passive, neck flexion and extension, to determine whether instability is present.\textsuperscript{70} With full neck flexion, the atlantoaxial joint interval increases, and the spinal canal diameter decreases. When these dimensions are exaggerated with flexion, cord compression is likely to be present.\textsuperscript{70} In addition, in this group of patients, not only odontoid dysplasia but also other cervical abnormalities, which may extend from the skull to the third cervical vertebra, may also be responsible for cervical instability and cord compression\textsuperscript{70} (fig. 6). Further CT, CT myelographic, or MRI examinations should be performed if clinical or roentgenographic findings are suggestive of spinal instability and cord compression (figs. 5 and 6).

Short-latency somatosensory evoked potentials monitoring is a useful noninvasive means of evaluating cord compression in dwarfs. The monitoring of evoked potentials is particularly useful in children to demonstrate cord compression before significant and perhaps irreversible clinical impairment develops.\textsuperscript{34,137,138}

\textbf{Anesthetic Management}

Care is necessary during induction of anesthesia and laryngoscopy to avoid positions of extreme flexion or extension, which can aggravate cord compression in patients with foramen magnum stenosis and cervical instability.\textsuperscript{74,75} Improper positioning of the head, neck, and shoulders during prolonged surgery in the supine position is particularly harmful and may lead to catastrophic intraoperative cord ischemia.\textsuperscript{74,75} In the patient with Morquio syndrome and atlantoaxial instability, if the shoulders, neck, and occiput rest on the same plane while the patient is lying in the supine position, the skull and atlas will be

\textbf{Fig. 6.} Four-year-old child with diastrophic dysplasia and cervical kyphosis. (A) Lateral cervical radiograph demonstrates anterior subluxation of C2 and C3, a typical finding in this dysplasia. (B) Cervical magnetic resonance image demonstrates the "bowstringing" of the spinal cord on the prominence of the posteriorly displaced hypoplastic C3 vertebra.
displaced anteriorly on the axis, compressing the cord. The same position in the patient with diastrophic dysplasia and cervical kyphosis can cause bowstringing of the cord within the spinal canal and result in ischemic myelopathy. The large occipital bossing of the achondroplasia results in anterior displacement of the head when the patient lies supine on a flat surface, such that the prominent posterior margin of the foramen magnum may indent the cervicomедullary junction. These complications can be prevented by placing a folded towel behind the shoulders, elevating them with respect to the occiput and restoring a neutral neck alignment. Cervical stabilizing devices such as a halo cast or a Milwaukee brace should be applied prior to anesthesia, for cervical fusion, to avoid cervical subluxation and dislocation. 159

In some patients whose necks are appropriately immobilized, laryngoscopy is impossible, particularly if other anomalies, such as a short neck, large tongue, or pectus carinatum co-exist. In such cases, fiberoptic intubation may be necessary. If spinal cord compression is associated with paresis and muscle wasting, succinylcholine is contraindicated, since this drug can cause life-threatening hyperkalemia in the presence of peripheral denervation. 140 Autonomic hyperreflexia is also a potential problem with cervical cord compression and myelopathy.

Anesthetizing a dwarf with raised ICP who, in addition, has the potential for upper airway obstruction, presents an enormous challenge for the anesthesiologist. An inhalation induction with a spontaneously breathing patient and a halogenated agent may be associated with hypercarbia and a consequent increase in ICP. An intravenous induction can result in unconsciousness and apnea in the patient who cannot be ventilated or intubated—a potential catastrophe if the patient has raised ICP. Balancing these conflicting requirements necessitates a case-by-case, careful determination of anesthetic priorities.

Suboccipital craniectomy for the relief of foramen magnum stenosis in patients with achondroplasia is often done with the patient in the sitting position. The expected complications associated with surgery in this position, such as air embolism, have been reported in these patients. 20 Other major intraoperative neurologic complications of this procedure include C1-level spinal cord infarction and brachial plexus palsies. 20 The intraoperative monitoring of somatosensory evoked potentials may help in the early detection of cord compression and ischemia, whether from foramen magnum stenosis, odontoid dysplasia, or spinal stenosis. 138, 141

**Thermal Regulation Dysfunction**

The hyperthermia that occasionally develops in patients with OI is not usually associated with the clinical features of malignant hyperthermia and should not be diagnosed as such. 90-92, 142 Therapy should consist of measures to provide external cooling. Sodium dantrolene administration is not indicated.

Although most of these hyperthermic episodes are not indicative of true malignant hyperthermia, a few cases with clinical features typical of true malignant hyperthermia have been described in patients with OI. 93, 143 In these patients, the diagnosis of malignant hyperthermia was not confirmed, however, by the caffeine contracture test. Anesthetic agents that precipitate malignant hyperthermia need not necessarily be avoided in patients with OI or in other dwarfs unless malignant hyperthermia is clinically suspected because of possible prior adverse anesthetic events in the patient or a family member.

**Coagulation Dysfunction**

The multifactorial nature of the hemostatic defects of patients with OI, the only one of the chondrodystrophies with an associated coagulopathy, has been reviewed above. Preoperative evaluation should include a test of bleeding time. 95 Platelets and fresh frozen plasma should be available in case bleeding becomes a problem. 95

**The Future**

**Dwarfism and Research**

Dramatic technological advances in molecular biology are beginning to define the underlying molecular and genetic abnormalities in some of the osteochondrodystrophies. Mutations that result in defects of cartilage components, such as collagen, or defects of the regulatory mechanisms of chondrogenesis are believed to cause this heterogeneous group of diseases.

Identification of the responsible type 1 collagen mutations have been detected in fibroblasts of some OI patients. 144 More recently, a single exon deletion has been demonstrated in the structure of the type II collagen gene in a large family with spondyloepiphyseal dysplasia. 145 Research, in the near future, will likely define gene defects in other chondrodystrophies as well. 146 This essential first step must be taken before the development of specific therapeutic gene manipulation can begin.

**Future Clinical Goals and Progress**

In addition to genetic advances, new surgical procedures to alter the phenotypes of some dwarfs have been developed. Although some of these modalities present medical, moral, and ethical dilemmas, it is likely that their application will become more widespread. 147, 148 Limb-lengthening orthopedic procedures, using a dynamic axial external fixation system to produce slow distraction of the callus (callostosis) or epiphysis (chondro-
diastasis) after corticotony, have achieved a normal trunk-to-lower-limb ratio in patients with achondroplasia. Such procedures, however, are sometimes complicated by the development of contractures, fractures, and non-union. Healing, sometimes painful, is protracted, averaging 10 months per limb. After leg-lengthening, these patients remain disproportionate because of short arms. Even if these are also lengthened, other problems associated with achondroplasia, such as upper airway abnormalities and spinal cord compression, persist and may still require therapy.

Recently, bone marrow transplantation has been performed in patients with MPS II, MPS III, MPS IV, and MPS VI in an attempt to replace the deficient lysosomal enzymes by providing a source of normal cells containing normal genes. This procedure has been associated with a reduction in glycosaminoglycan accumulation in liver, spleen, skin, cornea, and upper airway structures. Although less dramatic, neurologic improvement also has occurred in some patients. Glycosaminoglycan deposition in cartilage is not lessened, and bone changes in the MPS appear resistant to bone marrow transplantation. These studies are in their infancy and longer follow-up periods are necessary to evaluate their outcome.

The authors would like to thank Randall Wetzel, M.D. and Reed Pyeritz, M.D. for valuable critical advice and Susan Hacker for her excellent secretarial assistance.
